## TITLE OF THE INVENTION

IMAGE PROCESSING APPARATUS AND METHOD

## BACKGROUND OF THE INVENTION

Field of the Invention:

5    This invention relates to an image processing apparatus and method. More particularly, the invention relates to an image processing apparatus and method for high-efficiency encoding and recognition of images, as well as to an image processing apparatus and method for

10   detecting the feature points of an image.

Description of the Related Art:

Many image encoding techniques have been developed on the basis of filtering theory, which is based upon analysis of frequency regions, and information-source

15   encoding theory. Since the transformation process and inverse-transformation process of these theories have structures that are symmetrical to each other, the inverse transformation is self-evident and it is not required that one be aware of the inverse-transformation

20   process. For this reason, the conventional encoding is referred to as "symmetric encoding".

Symmetric encoding will be described in brief. First, the performance demanded by symmetric encoding is as follows:

(1)  Universality:  It is required that various types of image information be encodable efficiently.

(2)  Compatibility:  It is required that compatibility between image media having different

5    resolutions be assured.  To this end, there is need of a scheme through which bit strings for various image media having different resolutions are obtained if part of an encoded bit string is extracted.

(3)  Fidelity:  It is required that a reproduced

10   image be close to the original image.  This involves establishing the concept of distance between images for the purpose of evaluating fidelity.

Rapid progress in symmetric encoding has been made in recent years, and sub-band encoding in particular has

15   become the focus of much research for the following reasons:

(1)  A practical image processing scheme having a high degree of compatibility and suited to the service layer of image communication is capable of being

20   implement with ease.

(2)  A visual spatial frequency characteristic modeled accurately in the sub-band region can be reflected directly in the control of encoding parameters.

Described next will be the research trends and

technical level relating to transformation and quantization techniques, which are the requisite techniques of symmetric image encoding.

With regard to transformation techniques, studies

5    regarding prediction and orthogonal transformation have for the most part been completed, and investigations now proceeding deal mainly with band separating/synthesizing filters for sub-band encoding. The three capabilities required of a band separating/synthesizing filer are as

10   follows:

(1) Perfect reproducibility: In a case where an image is reproduced without performing encoding, it is required that the original signal be reproduced faithfully without causing distortion that accompanies

15   folding.

(2) Linear topological characteristic: It is required that the filter have a linear or near linear topological characteristic in image encoding.

(3) Orthogonality: There should be no overlapping

20   of filters for band separation.

At the present time, the only orthogonal filter of finite degree which truly satisfies the requirements of a linear topological characteristic and perfect reproducibility is the Haar filter (which is equivalent

to a second-order quadrature mirror filter).

With regard to quantization techniques, an encoding characteristic that is near ideal has attained an implementable technical level. In high-rate

5 quantization of an unstored information source, combining linear quantization and entropy encoding of a quantized output makes it possible to achieve quantization at a quantization loss of approximately 0.25 bit/sample in comparison with the rate-distortion

10 limit. In case of quantization at a lower rate, an excellent quantization performance can be realized by combining scalar quantization, which is equipped with a dead zone, and entropy encoding of a quantized output, wherein the entropy encoding includes zero-run encoding.

15 Furthermore, at a low rate, utilization of vector quantization also is possible. If use is made of lattice vector quantization or a multi-dimensional quantization method in which a code book is furnished with a certain algebraic structure, as in the manner of

20 a permutation code, multi-dimensional, high-efficiency quantization closer to the rate-distortion limit can be realized over a wide range of from low to high rates.

However, if an image occupies a major portion of the information handled, encoding which relies solely

upon geometric information of the information handled is insufficient. Accordingly, attempts to carry out compression utilizing the structure of an image, namely the structure of the actual world, have been studied

5   from several standpoints. These new attempts have already shown that there is no assurance that the transformation process and inverse-transformation process will be symmetrical. With such encoding, therefore, it is required that sufficient consideration

10  be given to the inverse-transformation process. Such encoding is referred to as "asymmetric encoding".

The foundation of the concept of a new type of image encoding (referred to as "asymmetric image encoding"), sometimes called "feature extraction

15  encoding" or "structure extraction encoding" does not necessarily depend completely upon filtering theory alone, as is the case with conventional image encoding techniques. With asymmetric image encoding, symbolizing and reproduction algorithms are required to have the

20  following properties:

(1) When an input image contains noise, it is required that fluctuation produced in a feature parameter by such noise be very small.

(2) A set of input images mapped onto identical

feature parameters owing to the symbolizing algorithm should be as small as possible. If possible, the symbolizing algorithm should be one-to-one mapping to feature and structure parameters from the input image.

5 The feature and structure parameter space and the symbolizing algorithm should be complete.

(3) The reproduction algorithm should be a stable, i.e., continuous mapping. More specifically, when noise due to coarse quantization appears in a feature

10 parameter extracted by the symbolizing algorithm, and even when the calculation accuracy is unsatisfactory, it is required that reproduction of an image close to the original image be assured.

(4) It should be possible to calculate both the

15 symbolizing algorithm and reproduction algorithm stably in numerical fashion and in a finite number of steps.

Asymmetric image encoding presently being studied can be classified as follows:

·Application of IFS (Integrated Function Systems)

20 The self-similarity (fractal property) believed to exist between partial images of an input image is utilized to find a reduced mapping proper to each partial image, and encoding is attempted on the basis thereof. At the present time, an affine transformation

is employed as the mapping.  Since a reproduced image is

given as a set of stable points in a dynamic system, the

image is decoded by recursive processing.

·Application of edge information

5       It has long been known that edges provide important

information in terms of visual information processing.

A complete description of an image can be achieved by

combining edge information and appropriate additional

information.  In an image encoding/decoding system that

10  employs edge information, the position of an edge is

extracted from an input image by an encoder, a certain

type of information (e.g., a differential coefficient)

at this edge position is extracted and the image is

reproduced by appropriate interpolation performed by a

15  decoder.

·Use of motion information

A method of estimating a motion vector as a feature

parameter and performing encoding using this vector was

been studied in the field of moving-picture encoding.

20  More specifically, a moving vector is predicted, three-

dimensional motion and a three-dimensional structure

(rule) are predicted on the basis of the predicted

vector, and on the basis of these a three-dimensional

structural (rule) model is constructed.  The image is

encoded/decoded using this three-dimensional structural (rule) model.

At the present time, it is assumed that when IFS is applied in image encoding, the fractal property appears

5  to the same degree over the entirety of one image. However, if a natural image is taken as an example, a plurality of objects will be present in one image. Therefore, the assumption that there is a fractal property over the entirety of the natural image can only

10  mean that the above method is fairly careless. Further, the employment of edge information or motion information involves many unsolved technical problems in terms of pattern recognition, learning of knowledge, etc.

As mentioned above, an edge is widely accepted as

15  the feature of an image. Here an edge refers to a portion of the image where there is a large amount of change in image intensity (luminance, density, saturation and hue). Edge position is detected as the position of the maximal value of the first-order

20  differential coefficient or as the position at which a second-order differential coefficient becomes zero. (See F. Ulupinar and G. Medioni: "Refining edges detected by a LOG operator", Computer vision, graphic and image processing, vol. 51, pp. 275 ~ 298, 1990.)

A method of detecting a singularity by multi-resolution analysis has been proposed. (See S. Mallat and W.L. Hwang: "Singularity detection and processing with wavelets", IEEE Trans. information theory, vol. 38,

5   no. 2, pp. 617 ~ 643, Mar. 1992.) This method performs detection based upon the fact that a singularity exhibits a maximal value over all frequency components.

However, since a first-order differential coefficient has the effect of emphasizing noise, a

10  method of detecting an edge from a first-order differential coefficient is susceptible to noise. Similarly, a method of detecting an edge from the zero-cross point of a second-order differential coefficient also is disadvantageous in that the precision of the

15  position of the detected edge is influenced strongly by noise. Further, a method of detecting an edge by multi-resolution analysis is highly resistant to the effects of noise but involves a large amount of calculation.

Furthermore, an edge detected by these methods

20  generally is continuous. If it is attempted to encode the original image based upon such an edge, it becomes necessary to execute some kind of threshold-value processing in order to select a finite number of feature points from a continuously existing edge.

## SUMMARY OF THE INVENTION

An object of the present invention is to provide an image processing apparatus and method in which it is possible to execute asymmetric encoding that does not require the extraction of three-dimensional motion and three-dimensional structures.

According to the present invention, the foregoing object is attained by providing an image processing apparatus, comprising: transformation means for transforming data space of an input image to multi-resolution space and outputting a multi-resolution representation of the input image; detecting means for detecting a singularity in the input image; extracting means for extracting a local pattern, which is formed by a spatial arrangement of intensities of the multi-resolution representation in a partial area containing the detected singularity, with regard to partial areas of a plurality of sizes; quantizing means for creating a quantization code book based upon the extracted local pattern and replacing the multi-resolution representation by a code word using the code book; and encoding means for algebraic encoding code data which includes position coordinates of the singularity in the multi-resolution representation and the code word

provided by the quantizing means.

Another object of the present invention is to provide an image processing apparatus and method in which image data are retrieved from a partial image by

5   applying the aforementioned apparatus and method to image recognition.

According to the present invention, the foregoing object is attained by providing an apparatus further comprising memory means for storing degree of conformity

10  or quantization error, calculated by the quantizing means, when the local pattern is allocated to a representative vector; and deciding means which, on the basis of the degree of conformity or quantization error, is for deciding the order relating to the perspective

15  depth between any two representative vectors contained in the code data; wherein the encoding means encodes the order relating to the perspective depth.

A further object of the present invention is to provide an image processing apparatus and method

20  strongly resistant to the effects of noise, in which a finite number of feature points can be readily obtained.

According to the present invention, the foregoing object is attained by providing an image processing apparatus comprising: input means for entering an image;

transformation means for transforming data of the input

image, which is represented by a function on a two-

dimensional plane entered by the input means, to data of

a vector field; detecting means for detecting a pole and

5   a zero point of image data transformed by the

transformation means; arithmetic means for calculating a

finite number of expansion coefficients of a polynomial

expansion about the pole detected by the detecting

means; and deciding means which, based upon the position

10   of each pole detected by the detecting means, is for

deciding an area in which a polynomial expansion of

finite degree obtained by the arithmetic means about

each pole can be approximated.

Other features and advantages of the present

15   invention will be apparent from the following

description taken in conjunction with the accompanying

drawings, in which like reference characters designate

the same or similar parts throughout the figures thereof.

BRIEF DESCRIPTION OF THE DRAWINGS

20 Fig. 10 is a diagram showing an example of division of an area by a transformation encoder illustrated in Fig. 7.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Embodiments of an image processing apparatus according to the present invention will now be described in detail with reference to the drawings.

First Embodiment

5    Fig. 1 is a block diagram illustrating the construction of an image processing apparatus according to an embodiment of the present invention.

As shown in Fig. 1, the apparatus includes an image input unit 101, such as an image scanner, for reading 10 the image of an original and producing an input image 151. The image input unit 101 is also capable of directly entering image data from an image processor or computer, not shown. The input image 151 is represented by Equation (1) shown below. Further, in a case where 15 the input image is given as a digital image, it will suffice to convert this equation to discrete points.

$$f(x), x \in R^2 \qquad (1)$$

A transformation unit 102 transforms the data space of the input image 151 to multi-resolution space. By 20 way of example, multi-resolution space is four-dimensional space defined by a one-dimensional scale parameter s, a two-dimensional shift parameter b and a one-dimensional rotation-angle parameter $\theta$. The input image 151 expressed in multi-resolution space is

referred to as a multi-resolution representation 152.
The transformation unit 102 performs a transformation in
accordance with Equations (2), (3), shown below. In
Equation (3), R(θ) represents a rotation matrix and $\phi_x$ a

5   function referred to as an analyzing wavelet, which
satisfies the condition of Equation (4) below. Further,
an image f is reproduced in the manner of Equation (5)
below.

$$< f, \phi_{s,b,\theta} > = \int_{R^2} dx \bar{\phi}_{s,b,\theta}(x) f(x) \qquad (2)$$

$$\phi_{s,b,\theta}(x) = s^{-1}\phi(R(\theta)^{-1}(\frac{x-b}{s})) \qquad (3)$$

$$C_\phi = (2\pi)^2 \int_0^\infty \frac{dr}{r} \int_0^{2\pi} d\theta | \phi(r\cos\theta, r\sin\theta) |^2 < \infty \qquad (4)$$

$$f = C_\phi^{-1} \int_0^\infty \frac{ds}{s^3} \int_{R^2} db \int_0^{2\pi} d\theta < f, \phi_{s,b,\theta} > \phi_{s,b,\theta} \qquad (5)$$

10      In actual calculation, a discrete multi-resolution
space is convenient. In this case, each parameter is
set in the manner indicated by Equation (6) below. In
Equation (6), j represents the depth of a local pattern,
defined later. This differs from the method of dealing

15  with parameters used ordinarily in that a shift
parameter in Equation (6) has a width $2^{Max(0,k-j)}$. As
shown in Fig. 2, the spatial sampling interval (the
offset between an interval indicated at 201 and an
interval indicated at 202) at a certain scale is equal

20  to a space width 203 of a wavelet base at a scale finer

than the above-mentioned scale by an amount equivalent to the depth of the local pattern.

$$
\left.\begin{array}{c}
s = 2^k \\
b = (2^{Max(0,k-j)} \lambda \Delta x, 2^{Max(0,k-j)} m\Delta y) \\
\theta = n\theta_0
\end{array}\right\} \qquad (6)
$$

In order to avoid confusion, real space coordinates

5 are adopted as two-dimensional coordinates in real space (the image), and coordinates in multi-resolution space are denoted by parameter coordinates. When those having rotational symmetry are employed as analyzing wavelets $\phi x$, the multi-resolution space becomes three-dimensional,

10 with the axis relating to the angle of rotation having omitted. In this embodiment, analyzing wavelets having rotational symmetry are employed in order to facilitate an understanding of the following discussion. However, the discussion would be similar even if the angle of

15 rotation were taken into account. In the diagram used for the purpose of explanation, real space is expressed by one dimension for the sake of simplicity. Transformation in case of a analyzing wavelets having rotational symmetry is performed as indicated by

20 Equation (7) below.

$$
< f, \phi_{s,b,} > = \int_x dx \overline{\phi}_{s,b} f_x, \phi_{s,b}(x) = s^{-1} \phi(\frac{x-b}{s}) \qquad (7)
$$

A transformation unit 103 transforms the multi-resolution representation 152 to a representation of local pattern space and outputs a local pattern 153. The neighborhood $N_\lambda(s_1, b_1)$ with depth $\lambda$ with respect to a

5  parameter coordinate $(s_1 = s^{k1}, b_1)$ is defined by Equations (8), (9) below. Fig. 3 is a diagram showing an example of a local pattern with depth $\lambda = 3$. This shows that if the parameter coordinates differ, then the region covered by the local pattern, namely the real

10  space region (the width b), and the scale region (which corresponds to the frequency region of width s) also differ.

$$s = 2^k, \quad k = \left\{ k_1, k_1 - 1, \cdots, Max(0, k_1 - \lambda) \right\} \qquad (8)$$

$$b = b_1 \pm \left( (m - \frac{1}{2}) 2^k \Delta x, (n - \frac{1}{2}) 2^k \Delta y \right), m, n = \left\{ 1, \cdots, 2^{k-k} \right\} \quad (9)$$

Thus, the neighborhood $N_\lambda(s_1, b_1)$ with depth $\lambda$ is

15  equal to a quad tree (a binary tree in Fig. 3) including the node $(s_1, b_1)$ as the root. The local pattern of parameter coordinates (s, b) with depth $\lambda$ is that obtained by making the value of the wavelet coefficient $\langle \phi_{sj, bk} \rangle$ at the parameter coordinates correspond to each

20  node of $N_\lambda(s, b)$. The local pattern space of depth $\lambda$ is

referred to as function space established by defining an
inner product, which is defined by Equation (10) below
as the set of the quad tree mentioned above (see Fig. 4).
The summation on the right-hand side of Equation (10)

5    extends over nodes belonging to the local pattern. The
local pattern space of depth $\lambda$ will be denoted by $T^\lambda$ and
elements thereof will be denoted by $t_n^\lambda \in T^\lambda$ hereinafter.

$$<< f, \phi_{s_0 s_0, b_0 + b} >, < g, \phi_{s_0 s_0, b + b} >>_{m,b} = \sum_{m,b} < f, \phi_{s_0 s_0, b_0 + b} >< g, \phi_{s_0 s_0, b_1 + b} > \qquad (10)$$

     On the basis of information representing the
10   parameter coordinates and depth sent from a quantizer
105, described later, the transformation unit 103
extracts the corresponding local patterns in discrete
multi-resolution space and maps them in local pattern
space of the respectively corresponding depths.
15   Furthermore, the transformation unit 103 counts the
frequency $p(t_n^\lambda)$ of appearance of each of the local
patterns $t_n^\lambda$ and stores this value.

     A singularity detector 1031 detects singularities
of an image that has been entered by the image input
20   unit 101. An edge detected by a Laplacian filter or
Canny filter or a feature point of the image may serve
as a singularity.

On the basis of the frequency $p(t_n^\lambda)$ of appearance

of the local patterns mentioned above, the code book

creating unit 104 registers a local pattern $t_n^\lambda$, at which

the appearance frequency p has exceeded a suitable value

5 (threshold value), in a code book as a representative

vector, and establishes a relationship between the

representative vector and a codeword. A jth

representative vector with depth $\lambda$ will be denoted by $d_n^\lambda$

hereinafter. It should be noted that there can be a

10 case in which the threshold value with respect to the

occurrence frequency p is set for every depth $\lambda$ and a

case in which the threshold value is set to be the same

for all depths $\lambda$.

A set of elements for which a set-theoretic order

15 relation hold true exists between a local pattern with

depth k and a local pattern with depth $\lambda$ (>k) (see Fig.

5. An inclusion-relation extractor 1041 connected to

the code book creation unit 104 investigates the

relation between local patterns having different depths.

20 The order relationship referred to here is indicated by

Equation (11) below. When trees coincide, this means

that the values of wavelet coefficients at each node

coincide. Though local patterns having different depths

are correlated by such an order relation, the actual

data contains an error. Therefore, representation as

indicated by Equation (12) below using the inner product

defined earlier is more realistic.

5        Among the partial trees $d_i^\lambda > d_j^k$, if and only if

there is at least one subtree of $d_i^\lambda$

which coincides with $d_j^k$        (11)

$d_i^\lambda > d_j^k$, if and only if there is at least one

subtree of $d_i^\lambda$ for which the inner product with $d_j^k$

10        is greater than a certain value        (12)

A quantizer 105 compares the multi-resolution

representation 152 with a representative vector in a

code book 154. The quantizer 105 performs the

comparison with regard to local patterns of all depths

15    for which representative vectors exist at each of the

parameter coordinates in multi-resolution space, and the

local patterns in the neighborhood of each of the

parameter coordinates are replaced by code words

corresponding to the representative vector $d_n^\lambda$ for which

20    the above-mentioned inner product is maximized, thereby

achieving encoding. In a case where the maximal value

of the inner product does not become greater than a

certain threshold value, the local pattern which is the

object of comparison is adopted as the candidate for a

representative vector and the parameter coordinates and

depth thereof are outputted to the transformation unit

103. As a result of this processing, correspondence

5    between appropriate code words and all parameter

coordinates of multi-resolution space is obtained.

A redundancy eliminating unit 106 compresses an

image 155 that has been encoded by the above-described

local pattern. The data encoded using the

10   representative vectors at each of the parameter

coordinates are redundant in the sense of the order

relation between representative vectors close to each

other in real space (see Fig. 5). Accordingly, among

the representative vectors supportive of which in real

15   space share a common region, the redundancy eliminating

unit 106 deletes unnecessary representative vectors

using the set-theoretical order relation extracted by

the inclusion-relation extractor 1041.

A perspective-order computation unit 107 extracts

20   the perspective-order relationship with respect to real

depth in the real space of real objects represented by

representative vectors from a signal 156 outputted by

the redundancy eliminating unit 106. There exists some

pairs of representative vectors close to each other in

the real space supportive of which in real space share a
common region.  Accordingly, these perspective-order
relationships can be obtained depending upon which of
two representative vectors in nearer than the other to
5  the wavelet coefficients in the common region.  This
will be described with reference to Fig. 6.

In order to encode local patterns neighboring each
of the parameter coordinates, the quantizer 105
calculates the inner product of the representative
10  vectors.  If a representative vector regarding an object
situated at the most forward position in real space has
been acquired and this object is not hidden by anything,
the inner product between this representative vector and
a local pattern corresponding to this object will
15  coincide with the norm of the representative vector in a
state in which there is no measured error.  Local
patterns 601 and 602 in Fig. 6 are local patterns
corresponding to such an object (situated at the most
forward position).

20  A local pattern 603 shown in Fig. 6 is a local
pattern corresponding to an object hidden by another
object.  A common region shared by the support of the
local pattern 603 and that of the other object (i.e.,
the local pattern 602) in real space is $b_{10}$ and $b_{11}$.  In

a region other than this shared region (namely a region extending from b11 to b 13), the inner product between the representative vectors corresponding thereto should coincide with the norm. In other words, in the shared

5   regions b10 and b11, it can be predicted that the object 603 will be hidden by the object 602. Thus, by ascertaining the inner product between representative vectors at each of the parameter coordinates, the perspective-order relationship of the respective local

10  pattern can be determined.

An algebraic encoder 108 algebraically encodes an output signal 157 from the perspective-order computation unit 107, namely a code word, real space coordinates, rotation and scale of a singularity and perspective-

15  order information, and outputs a code 158. The outputted code 158 is stored in a memory (not shown) or transmitted via a line.

An algebraic decoder 109 algebraically decodes the code 158, which has entered from a memory or line. An

20  inverse quantizer 110 generates local patterns from the code word contained in the algebraically decoded signal 159 and outputs the local patterns as a signal 160 indicative of the multi-resolution representation.

On the basis of the algebraically decoded real

space coordinates, rotation, scale and perspective-order information, an image synthesizer 111 combines at least two local patterns, which have been generated by the inverse quantizer 110, into a single image. The signal 160 is expressed in multi-resolution space. An inverse transformation unit 112 inversely transforms the image (the multi-resolution representation), which has been synthesized by the image synthesizer 111, to a function in real space and outputs a signal 162 indicative of this function.

An image output unit 113 is a printer or display and forms or displays the image represented by the signal 162. The image output unit 113 stores the signal 162 on a recording medium or outputs the signal 162 to an image processor or computer, not shown.

An example has been described in which the transformation unit 102 transforms the input image 151 to multi-resolution space. However, it is also effective to transform the input image 151 to a multi-resolution pyramid. This method involves dividing the original image into several (e.g., four) partial images, obtaining the mean of the pixel values of each of the partial images, subdividing the partial images into several partial images and obtaining the mean of each

image. By repeating this processing, a multi-resolution space approximation of the original image can be obtained.

Thus, in accordance with this embodiment, each
5    input image can be expressed by a plurality of code words as well as the positions and sizes thereof or by the perspective-order relationship of the representative vectors. Further, though innumerable images can be generated by movement of a finite number of rigid bodies,
10   this embodiment makes it possible to compactly express an image set of this type.

More specifically, this embodiment has the following effects:

(1)  The perspective-order computation unit
15   extracts information indicative of a plurality of code words, positions corresponding thereto and/or angle of rotation and/or scale, as well as information representing the perspective-order relationship of any two of these representative vectors, contained in the
20   input image outputted by the quantizer. On the basis of the extracted information, the encoder encodes the input image. This makes it possible to achieve highly efficient encoding.

(2)  The perspective-order computation unit

compares the local patterns of one image with those of another one using the information extracted in (1) above. As a result, the comparison of the local patterns of any two images can be performed with ease.

5     (3) If (2) above is applied to an image recognition apparatus, retrieval of image data from partial images can be performed with ease.

    (4) By combining the encoding apparatus described in (1) above and a decoding apparatus having the 10 algebraic decoder 109, the inverse quantizer 110 which generates local patterns from a plurality of code words resulting from decoding and the image synthesizer 111 for synthesizing local patterns by positions, rotation angles and sizes corresponding to the generated local 15 patterns and the information representing the perspective-order relationship of any two representative vectors, the amount of data transmitted, if image data are to be transmitted, is greatly reduced and the number of items of data (images) capable of being stored in a 20 memory device can be increased.

Second Embodiment

    Fig. 7 is a block diagram illustrating the construction of an image processing apparatus according to a second embodiment of the present invention.

As shown in Fig. 7, the apparatus includes an image input unit 1108 having a wide-view lens 1101, an array sensor 1102 and an input-parameter controller 1106, the details of which will be described later. Light that

5 has passed through the wide-angle lens 1101 impinges upon the array sensor 1102, which converts the light to an image signal and outputs the image signal.

A transformation unit 1103 applies processing, described later, to the image signal that has entered

10 from the image input unit 1108. A singularity detector 1104 applies processing, described later, to a signal that has entered from the transformation unit 1103. A transformation encoder 1105 applies processing, described later, to a signal that has entered from the

15 singularity detector 1104 and outputs a code to an information processor 1107.

[Wide-view lens 1101]

Fig. 8 is a diagram showing an example of a coordinate transformation performed by the wide-view

20 lens 1101. In Fig. 8, x represents the radius of a polar coordinate system on an image plane situated on the front side of the input system, an t represents the radius of the polar coordinate system after a transformation performed by the wide-view lens 1101.

Since this optical system is rotationally symmetric, the description given below will rendered solely with regard to the radial direction.

If we let $\phi$ represent the angle of incidence with respect to the optic axis and $\xi$ the focal length of a lens having the radius of the circle shown in Fig. 8, the radii t and x will be represented by the following equations, respectively:

$$t = 2\xi \tan(\phi / 2) \qquad (13)$$
$$x = \xi \tan(\phi) \qquad (14)$$

On the basis of Equations (13), (14), the radius x can be expressed by the equation below as a function of the radius t. This is the coordinate transformation in the wide-view lens 1101.

$$x = \frac{t}{1-(\frac{t}{2\xi})^2} \qquad (15)$$

The pattern (function) of frequency f(0), in the radial direction, which spreads over the entirety of the image plane is changed to the following function by the wide-view lens 1101:

$$f(t) = f(0)\frac{\{1-(\frac{t}{2\xi})^2\}^2}{1+(\frac{t}{2\xi})^2} \qquad (16)$$

Of course, in a case where an arbitrary object present in three-dimensional space is adopted as the

subject, it will suffice to know only the relationship between the incidence angle $\phi$ and the radius t. Accordingly, the coordinate transformation becomes as follows:

5

$$t = 2\xi \tan(\phi / 2) \qquad (17)$$

The coordinate transformation performed by the wide-view lens 1101 described above is a conformal map. Accordingly, singularities not present in the original image do not arise.

10 [Array sensor 1102]

If we let $\phi_j(x)$ represent the integral kernel, the output $g_j$ of a jth (counting from the center of the optic axis) array sensor 1102 will be represented by the following:

$$g_j = <\phi_j(x(t;\xi)) \mid f(x(t;\xi))>$$

15

$$= \int_{-\infty}^{+\infty} dt \, \overline{\phi}_j(x(t;\xi)) f(x(t;\xi)) \qquad (18)$$

[Transformation unit 1103]

The transformation unit 1103 causes a gradient $\nabla$ to act upon an image $f(x,y)$ which is a function in two-dimensional space, thereby generating a vector field.

$$g(x, y) = \nabla f(x, y)$$

20

$$= e1 \frac{\partial f}{\partial x} + e2 \frac{\partial f}{\partial y} \qquad (19)$$

where e1,e2 are components of basis.

Further, g(x,y) can be expressed as follows:

$$g(z) = r(z)\exp(\theta(z)) \qquad (20)$$

$$z = x + iy \qquad (21)$$

$$r(z) = \|\nabla f(x,y)\| = \sqrt{(df\,/\,dx)^2 + (df\,/\,dy)^2} \qquad (22)$$

$$\theta(z) = \arg(\nabla f(x,y)) = \arctan(\frac{df\,/\,dy}{df\,/\,dx}) \qquad (23)$$

Complex representation is used in the description

given below.

[Singularity detector 1104]

The singularity detector 1104 detects singularities
by utilizing the argument principle. The argument
principle will now be described. Let a function f(z) be
a meromorphic in a simply-connected region D, and let C
represent a simple closed curve having a positive
direction within D. Assume that there is neither a zero
point nor pole present on the closed curve C. In the
interior of the closed curve C, assume that the function
f(z) has a zero point of order $\lambda_k$ at each of $a_k$ (k = 1,
2, $\cdots$, m) and a pole of order $\mu_k$ at each of $b_k$ (k = 1,
2, $\cdots$, n). When starting from a point $z_0$ on the closed
curve C and returning to the point $z_0$ upon making one
full revolution of the closed curve, the amount of
increase $\Delta c \arg[f(z)]$ of the argument of the function

f(z) is given by the following equation if we let $N_z$, $N_p$ represent the numbers of zero points and poles, respectively, within the closed curve C:

$$\Delta c \arg(f(z)) = 2\pi\{N_z(f) - N_p(f)\} \qquad (24)$$

5       A method of utilizing the argument principle to detect a feature point of a vector field $\{g_{m,n}\}_{m,n}$ quantized in space will now be described.

Step 1:  Any point $z_{k,p} = \gamma_{k,p} \cdot \exp(\theta_{k,p})$ in a defined region of an image is selected.

10      Step 2:  A circle C centered on $z_{k,p}$ and having a suitable radius $\rho$ is considered.

If this operation is performed, the following equation holds true with respect to a number $N_z(g) = \sum \lambda_k$ of zero points and a number $N_p(z) = \sum \mu_k$ of poles, which

15    reside within the circle C, of the complex function g(z) in consideration of their orders obtained by the vector-field constructing unit (transformation unit 1103) in accordance with the argument principle.

$$N_z(g) - N_p(g) = \frac{\Delta c \arg g(z)}{2\pi} \qquad (25)$$

20    Accordingly, by considering a circle having a radius of one pixel and centered on each pixel of a given image, the difference between the numbers of zero

points and poles at all pixels is obtained using the
above-described argument principle. At this time, the
zero points or poles included in each circle are
considered to be one at most. Therefore, a zero point

5   is included when the right side of Equation (25) is
positive and a pole is included when the right side of
Equation (25) is negative. Accordingly, a center pixel
when a pole is determined to be present is detected as
the position of a singularity.

10      Here $\Delta c$ arg[g(z)] is calculated in the manner
described below (see Fig. 9, which illustrates an
integration path). The integration path may be a closed
curve and is not limited the size shown in Fig. 9.

$$
\begin{aligned}
\Delta c \, \text{arg}(g(z))|_{z=z_{m,n}} \\
\cong \gamma(g(z_{m+1,n+1}), g(z_{m+1,n})) + \gamma(g(z_{m,n+1}), g(z_{m+1,n+1})) \\
+ \gamma(g(z_{m-1,n+1}), g(z_{m,n+1})) + \gamma(g(z_{m-1,n}), g(z_{m-1,n+1})) \\
+ \gamma(g(z_{m-1,n-1}), g(z_{m-1,n})) + \gamma(g(z_{m,n-1}), g(z_{m-1,n-1})) \\
+ \gamma(g(z_{m+1,n-1}), g(z_{m,n-1})) + \gamma(g(z_{m+1,n}), g(z_{m+1,n-1}))
\end{aligned} \tag{26}
$$

15
$$
\gamma(x,y) = \begin{cases} \arg x - \arg y & \text{if} \quad \arg x - \arg y \le \pi \\ \arg y - \arg x & \text{otherwise} \end{cases} \tag{27}
$$

[Transformation encoder 1105]

In order to divide the defined region of a vector
field into a plurality of areas based upon the positions
of poles, it will suffice to divide the defined region

20  in such a manner that only one pole, for example, is

included (see Fig. 10, which shows an example of dividing a region). If this expedient is adopted, convergence of the Laurent series around the pole is guaranteed in each region except the pole.

5      In order to functionally approximate the partitioned vector field around each pole in the range of the region corresponding thereto, if the positions of the poles and zero points within the partial area $D_j$ as well as the order are already known, the function $w(z)$

10    can be expressed by Equations (28) through (30) below based upon the pole positions and orders $a_j, m_j$ ($j = 1, 2, \cdots, J$) and the zero-point positions and orders $b_k, n_k$ ($k = 1, 2, \cdots, K$). In a case where the zero point position and order cannot be specified, an orthogonal

15    polynomial expansion can be employed. By using the Laurent series expansion around each pole to approximate each region, a reduction in error can be expected in a case where a large area is expressed by one function.

$$w(z) = \sum_j c_{-j}(z - a_j)^{-m_j} + \sum_k c_k(z - b_k)^n \quad (28)$$

$$c_{-j} = \frac{1}{2\pi i}\oint_{\partial D_{-j}} d\eta \frac{w(\eta)}{(\eta - a_j)^{-j+1}} \quad (29)$$

$$c_k = \frac{1}{2\pi i}\oint_{\partial D_k} d\eta \frac{w(\eta)}{(\eta - b_k)^{k+1}} \quad (30)$$

20    [Input-parameter controller 1106]

The input-parameter controller 1106 controls the rotational angle of the optic axis of wide-view lens 1101 based upon control information of the rotational angle of the optic axis that has entered from the

5    information processor 1107. The information processor 1106 calculates the amount of control of the rotational angle of the optic axis in such a manner that a singularity is taken on the optic axis.

Thus, by regarding visual information, which serves

10   as a function on a two-dimensional plane, as one variable complex function, it is assured that the poles and zero points of the complex function will be isolated so long as the function is not a constant. In a case where the function is a constant, it will not contain

15   any information and may therefore be ignored. Accordingly, in accordance with this embodiment, a finite number of singularities can be obtained naturally and with facility.

The apparatus is strongly resistant to noise. For

20   example, impulse noise is detected as an edge in the method that relies upon both first-order and second-order differentiation. However, in the method of generating a vector field and detecting the singularity thereof, impulse noise is detected as a zero point.

Accordingly, if a pole is employed as a singularity, as mentioned above, impulse noise has no effect whatsoever upon singularity detection. Adopting a pole and not a zero point as a singularity is appropriate from the

5   viewpoint of function approximation. The reason for this is that the deciding factor of converging radius in case of series expansion is the position of a pole; a zero point plays no part whatsoever.

Thus, this embodiment can be suitably applied to

10  image processing such as extraction of feature points and encoding/decoding of images.

Other Embodiment

The present invention can be applied to a system

15  constituted by a plurality of devices (e.g., host computer, interface, reader, printer) or to an apparatus comprising a single device (e.g., copy machine, facsimile).

Further, the object of the present invention can be

20  also achieved by providing a storage medium storing program codes for performing the aforesaid processes to a system or an apparatus, reading the program codes with a computer (e.g., CPU, MPU) of the system or apparatus from the storage medium, then executing the program.

In this case, the program codes read from the storage medium realize the functions according to the embodiments, and the storage medium storing the program codes constitutes the invention.

5    Further, the storage medium, such as a floppy disk, a hard disk, an optical disk, a magneto-optical disk, CD-ROM, CD-R, a magnetic tape, a non-volatile type memory card, and ROM can be used for providing the program codes.

10   Furthermore, besides aforesaid functions according to the above embodiments are realized by executing the program codes which are read by a computer, the present invention includes a case where an OS (operating system) or the like working on the computer performs a part or

15   entire processes in accordance with designations of the program codes and realizes functions according to the above embodiments.

Furthermore, the present invention also includes a case where, after the program codes read from the

20   storage medium are written in a function expansion card which is inserted into the computer or in a memory provided in a function expansion unit which is connected to the computer, CPU or the like contained in the function expansion card or unit performs a part or

entire process in accordance with designations of the
program codes and realizes functions of the above
embodiments.

As many apparently widely different embodiments of
5    the present invention can be made without departing from
the spirit and scope thereof, it is to be understood
that the invention is not limited to the specific
embodiments thereof except as defined in the appended
claims.
